We may infer from Figure 2 that the DC link capacitor's AC ripple current I_{cap} arises from two main contributors: (1) the incoming current from the energy source and (2) the current drawn by the inverter. Capacitors cannot pass DC current; thus, DC current only flows from the source to the inverter, bypassing the capacitor.

Since the control mode of the grid-side converter is uncontrolled rectification in this process, the uncontrolled DC-link voltage is stabilized at 910 V. In the holding stage, the FESS neither stores energy nor releases energy, but the DC-link voltage is adjusted to 1000 V to satisfy the pre-discharging condition.

Accompanied by periodic charging and discharging of the capacitor, it causes heating of the capacitor. The DC-link capacitor is used for energy exchange between the front voltage source and the rear chopper, balancing the power difference between the front and rear stages, suppressing dc-link voltage ripple, and storing energy.

The term DC link has traditionally referred to the junction between two power conversion stages where an energy storage element (almost always a capacitor) acts as a buffer for each. A classic example is the capacitor placed between the rectifier and the voltage source inverter in a mains-supplied variable frequency drive (see Fig. 1).

When sizing a DC link capacitor for inverter applications, the ripple current requirement typically ends up being the limiting factor [1] [2] and drives which capacitor is selected. Ripple current, in this context, is referring to the AC current the capacitor must supply to the power bridges and the motor.

Single-phase grid-connected photovoltaic (PV) inverters (GCI) are commonly used to feed power back to the utility. However, the inverter output power fluctuates at 100 Hz, which can be seen by the PV panel, and this reduces the PV output power.
